1 Introduction

- mbeddr is a language and ide for embedded programming that facilitates programming by providing higher level language mechanisms
- parallel programming is becoming ever more important
- yet, mbeddr is still lacking higher-level support for parallel programming
- compared to library extensions language based support for pp features multiple benefits: individual problem-specific syntax, reduction of erroneous input by type system enhancements, program-wide optimization of generated code
- short examples for benefits
- ParallelMbeddr introduces task-based explicit parallel programming with shared memory that can be synchronized
- Objectives: appropriate syntax, type system support for safer code, optimized output
- outline of the work

Kommentar von Bastian

Question: Introduce example that is later used for the evaluation already here for motivational reasons?

2 Background

2.1 Processes and Threads

Every program in (delayed or interrupted) execution is represented by a process. A process typically has its own protected data (via virtual memory) and execution state and consists of one or more threads. A thread, also known as lightweight process, shares some of the memory with its process but has its own execution state and thread-local storage as needed[?, p. 20]. In the course of programming language and operating system development several variants of threads have been devised, among others green threads, fibers and coroutines which mainly differ in how they are managed.

2.2 Parallelism and concurrency

If multiple threads are “in the middle of executing code at the same time”[15, p. 124(?)] they are processed concurrently. They can actually be executed at the same time on different processors or interleaved on a single processor. The former is further called parallelism. Parallelism generalized to “the quality of occurring at the same time”[6, p. 91] can manifest in different ways. TODO: consider mentioning data races that are involved with both execution models

2.3 Types of parallelism

At least four different kinds of parallelism have been conceived. From an application programmer’s view seen at a very low level of the computer exist bit-level parallelism and instruction-level parallelism. Bit-level parallelism is concerned with increasing the word size of processors in order to reduce the amount of cycles that are needed to perform an instruction[5, p. 15]. Instruction-level parallelism, also called pipelining, is the simultaneous utilization of multiple stages of the execution pipeline of the processor. Both bit-level parallelism and instruction-level parallelism primarily reside on the hardware level and the operating system level and are, thus, no subject of this work. Data parallelism is present if the same calculation is performed on multiple sets of data and can be regarded as a specialization of task parallelism which denotes the simultaneous execution of different calculations “on either the same or different data”[5, p. 125]. The latter being the more general approach to software-level parallelism is the subject of this work.

2.4 Data races

With multiple threads running in parallel and having access to the shared data of their process a second class of errors that is unique to parallel (and distributed) programming arises. These so-called synchronisation errors occur due to data races and are a result of the general non-atomicity of computations and memory references. Data races— also known as race conditions— are defined as at least “two unsynchronised memory references by two processes on one memory location, of which at least one reference is a write access”[7, p. 327]¹. Such data races can result in inconsistent program states and non-deterministic program behavior since the order in which the concerned memory is accessed might change. In order to deal with this issue three main paradigms have been conceived in parallel programming.

¹ As the definition implies data races are not limited to threads and the shared process data. E.g. file-based race conditions can even occur between two different processes[25]. Since this work is about parallelization of single processes other kinds of race conditions are not further considered.

2.5 Communication model: shared memory

The memory model that underlied the former treatment of processes that share some data with their threads is formally known as *shared memory*. In this model communication between entities is realized by shared-memory regions which are written to and read from [10, p. 138]². Data races can be avoided with help of the low-level the synchronization primitive *mutex*³. A mutex can be locked by exactly one thread. Any other thread that tries to lock the same mutex is blocked until the locking thread releases the mutex [16]. Thus, code regions can be protected by having threads synchronize over mutexes that protect these regions. One of the disadvantages of mutexes is that they are not tightly coupled to the data or computation that they protect. It is the programmer's duty to take care of the sane utilization of a certain mutex. Therefore various higher-level synchronization measures like monitors in Java (TODO: forward reference) and synchronized classes in D (TODO: forward reference) were developed. These measures are usually built on top of mutexes [14, p. 25]. Another disadvantage of mutexes is their vulnerability for deadlocks which means that multiple processes are in a state where "each is waiting for release of a resource which currently held by some other process" [2, p. 119] such that no progress will ever finish executing [8, p. 2-3].

2.6 Communication model: message passing

Whereas communication in the shared memory paradigm happens rather implicitly it is done explicitly in the *message passing* paradigm. Message passing originates from Hoare's paper on Communicating Sequential Processes (CSP) (TODO: reference!). In CSP messages are sent from one entity to another. "The sender waits until the receiver has accepted the message (*synchronous* message passing)" [22, p. 138]. Message passing with asynchronous message sends were deployed by the actor model [13] and pi calculus [19]. Although message passing avoids shared data and realizes communication generally via copies of data⁴ it still suffers from potential race conditions [20].

2.7 Communication model: transactional memory

Transactional memory provides a non-blocking⁵ memory model which enables communication via "lightweight, *in-memory* transactions" [9, p. 3] which are code blocks that from a programmer's perspective are executed atomically. The illusion of atomicity is realized by the underlying transaction system which may execute transactions in parallel and has to take care of conflicting reads and writes in transactions⁶ [12]. Transactional memory can either be realized in hardware or in software. While the former promises a better performance it demands specific hardware. Software transactional memory on the other hand seems to suffer from comparatively "poor performance" [3, p. 13].

2.8 Coarse- and fine-grained synchronization

In order to keep structures and computations synchronized the simplest approach to avoid data races is to use the available measures like locks or transactions as broadly as possible. E.g. transactions could be widened to hold every operation a thread has to execute. As every synchronization is basically a serialization of otherwise parallel executed code such coarse-grained synchronization would eliminate the benefits of parallel execution. On the other hand fine-grained synchronization can introduce race conditions if the programmer misses some locking policy. In addition the acquisition of every lock takes time which can become an issue with increasing locking counts. Therefore a trade-off between locking-overhead and scalability problems has to be found [9, pp. 1-2].

² As for race conditions the model is not limited to intra-process communication via threads or similar approaches to parallelization. Communication between two process can also be realized via shared memory but is not in the scope of this work.

³ Semaphores as a second synchronization primitive are closely related to mutexes. Since they do not provide further insights for the discussion they are not further investigated in this work.

⁴ Actually shared data is often used in implementations of message passing models in order to enhance the performance. Furthermore it exists on the language level like in terms of monitors that were developed by Hoare to reduce deadlocks in CSP. The main notion of the message passing concept nevertheless goes without shared data.

⁵ TODO: explain

⁶ To this end the corresponding transactions may need to be reexecuted as a whole.

2.9 Embedded programming

“An embedded system is a computerized system that is purpose-built for its application.”[27, p. 1] Due to its narrow scope and monetary constraints induced by the application domain the hardware of such systems is often constrained to the point that it just accomplishes the job[27]. Thus, the memory consumption of the resulting program is one main issue to be considered in embedded programming. Additionally, for real-time systems which constitute a subclass of embedded systems not only the correctness of computations but also the consumed time determine their quality and usefulness [4, pp. 1-2]. Therefore the predictability of the program’s execution time becomes an issue for real-time systems⁷.

2.10 MPS and mbeddr

“JetBrains MPS⁸ is an open source [...] language workbench developed over the last ten years by JetBrains. ”[26] As such it provides an projectional editor which lets the user directly work on the abstract syntax tree (AST) of the program[1]. It supports the development and composition of potentially syntactically ambiguous modular language extensions in combination with the development of integrated development environments or extensions thereof. Mbeddr is an extension of MPS tailored for the embedded software development in C. Every program written in the mbeddr IDE is translated to C99 source code which are then be further processed by the gcc tool chain⁹. The implementation of C in mbeddr does not only provide extensions to the core of C but also has a few differences to the basis of C99. They will be introduced as needed.

TODO: Add explanations for MPS aspects, type-system checking rules... as needed

TODO: Maybe add section for explicit vs. implicit parallel programming, look at Programming Distributed Systems by H. E. Bal, pp. 113-114

TODO: Implementation: coarse- vs. fine-grained synchronization, problems => implicit synchronization not exhaustive => optimization for safe lock avoidance helpful

⁷ Mbeddr(TODO: forward reference) does not have first-class support for the quantification of related parameters like the worst-case execution time (WCET)[4, p. 8], yet. For this reason predictability is a lesser concern of this thesis and will be reflected primarily in the careful consideration of the CPU consumption and processing time of the implementation.

3 Design and Implementation

In this chapter extension of mbeddr for parallel programming, called ParallelMbeddr, is introduced. To this end the new language features for C are explained each in terms of the design and the translation to plain mbeddr C code. In order to illustrate the presented features a running example is incrementally built. Further examples are depicted whenever the running example does not provide the right structure to clarify a feature. Whenever necessary relevant details of the implementation in mbeddr are briefly depicted.

3.1 Tasks

The basic parallelization element is a *task*. It denotes a parallel unit of execution and, as the name suggests, aims at task parallelism. As the implementation of the underlying parallelization technique might change in the future it is reasonable to abstract the terminology from it. The most basic task which always exists executes the code of the entry function of the program. A task can also be regarded as a closure of the expression that shall be run in parallel. The reader should distinguish this ‘execution template’ from the actual running instance of a task. The latter will further on be addressed as a *running task*.

3.1.1 Design

The syntax e of expressions in mbeddr is extended by

$e ::= \dots \mid |e|$

When executed a task term yields a handle to a parallel unit of execution. This way the initialization of the task and the actual execution are decoupled and can happen independently. When a task is run the embraced expression is executed and its value is returned. If the type of the expression is void no value will be returned. The type of a task reflects this return value.

$t ::= \dots \mid \text{Task}<t>$

Due to implementation reasons (TODO: ref) the embraced return type of a task must be either void or a pointer to the type of the embraced expression:

$$\text{VoidTask} \frac{e \vdash \text{void}}{|e| \vdash \text{Task}<\text{void}>} \qquad \text{NonVoidTask} \frac{e \vdash t \quad t \neq \text{void}}{|e| \vdash \text{Task}<\text{void}*>}$$

When a task is not used anymore to produce running instances of itself it should be cleared in order to free the memory that it implicitly occupies on the heap:

$e ::= \dots \mid e.\text{clear}$

$$\text{VoidTask} \frac{|e| \vdash \text{Task}<\text{void}>}{\text{void}}$$

If a task is copied by the pass-by-value semantics of C the copied task will share the heap-managed data, the reference environment of its free variables, with the original task. Therefore a task needs to be cleared only once in order to avoid memory leaks. Keep in mind that a running instance of a task will not be affected by clearing the task by that it was created.

3.1.2 Translation

The pthreads library was chosen as a means to realize concurrency in the translation. It supports all necessary parallelization features and provides a more direct control of the generated code as opposed to frameworks like OpenMP (TODO: reference). Every task in ParallelMbeddr is represented by a thread as provided by the POSIX threads standard. As the thread initialization function of pthreads takes a function pointer of type **void* -> void*** the computation of the translated task is represented by an according function:

```
1 || void* parFun_X(void* voidArgs) {...}
```

The **X** in the name symbolizes that for every task a unique adaptee of this function with the prefix **parFun_** and some unique suffix chosen by the framework is generated¹⁰.

If a task contains any references to local variables or function arguments they need to be bound to capture the variable state at the time of the task initialization. Such state is represented by an argument struct:

```
1 || struct Args_X {
2 ||     t_1 v_1;
3 ||     ...
4 ||     t_n v_n;
5 || }
```

where every **v_i** represents an equally named reference in the task expression to a variable of type **t_i**.

The generated function **parFun_X** is then given an instance of **Args_X** which it uses to bind the references of the task expression to. The full function definition of a task **e** of type **Task<t*>** is, thus:

```
1 || void* parFun_X(void* voidArgs) {
2 ||     t* result = malloc(sizeof(t));
3 ||     Args_X* args = (Args_X*) voidArgs;
4 ||     *result = e';
5 ||     return result;
6 || }
```

where **e'** is the expression obtained when every local variable reference and function argument reference **r** in **e** is substituted by a reference to an equally named and typed field in **args**:

r / args->r

If the embraced expression of a task does not contain any reference of this kind (e.g. only references to global variables) the **args** definition line is omitted as is clearly the—otherwise empty—declaration of **struct Args_X**. In this case **e'** equals **e**.

The generated function of a task of type **Task<void>** renounces the result-related statements:

```
1 || void* parFun_X(void* voidArgs) {
2 ||     t* result = malloc(sizeof(t));
3 ||     Args_X* args = (Args_X*) voidArgs;
4 ||     e';
5 || }
```

Again, any argument-related code is generated as needed.

The aforementioned handle that a task yields is represented by an instance of a corresponding struct that captures both the initialization state and the computation of the embraced expression¹¹. As the void pointer of the arguments does not keep their type information and therefore their size an additional field **argsSize** is needed in order to be able to create copies of the arguments later on (TODO forwarded ref).

```
1 || exported struct Task {
2 ||     void* args;
3 ||     (void*) => (void*) fun;
4 ||     size_t argsSize;
5 || }
```

As opposed to the unique definitions of other elements that need to be defined for every occurrence of a task (the ones with the **X** suffixes) **struct Task** is generic and is reused for every task. Generic declarations are kept in fixed separately generated modules and are imported into the user-defined modules. With these components in mind the actual translation of a task expression **| . |** that contains references **v_i** to **v_n** becomes an mbeddr block expression¹²:

¹⁰ In the following explanations **X** will always denote some arbitrary suffix. Keep in mind that these suffixes do not necessarily coincide for different kinds of components.

¹¹ **(void*) => (void*) fun** is mbeddr syntax for the not easily edible function pointer **void *(*fun) (void *)** in standard C99

¹² A block expression contains a list of statements of which the mandatory yield statement returns the result value.

```

1 | {
2 |   Args_X* args_X = malloc(sizeof(Args_X));
3 |   args_X->v_1 = v_1;
4 |   ...
5 |   args_X->v_n = v_n;
6 |   yield (Task){ args_X, parFun_X, sizeof(Args_X) };
7 | }

```

⇒

```

1 | taskInit(v_1, ..., v_n)
   | with
1 | inline Args_X taskInit(t_1 v_1, ..., t_n v_n) {
2 |   Args_X* args_X = malloc(sizeof(Args_X));
3 |   args_X->v_1 = v_1;
4 |   ...
5 |   args_X->v_n = v_n;
6 |   return (Task){ args_X, parFun_X, sizeof(Args_X) };
7 | }

```

The expression of the **yield** statement is a compound literal which on evaluation creates an instance of the aforementioned **struct Task**. The block expression is then further reduced by mbeddr to a call of a newly generated inline function¹³.

Without any references to bind a task is just reduced to the compound literal:

```

1 | (Task_X){ null, parFun_X, 0 }

```

By above definition of **parFun_X** it becomes clear that the output of a task is routed via the heap instead of the stack. Additionally the arguments of a task—its environment—are stored on the heap before execution. This approach was chosen mainly in order to simplify the generation of the resulting code. In exchange both the result and the arguments of a task have to be deleted by the programmer by hand. Since the result is returned via a pointer onto the heap it becomes obvious that the return type of a task must either be a void type or a pointer type. Concerning task arguments one advantage of this implementation is that a task may be passed by value, e.g. when using a builder function to create tasks, without the possible need to copy multiple arguments. Instead just the pointer to the heap-managed data is copied. As will be shown in the (FUTURE WORK) chapter a stack-based implementation of task (I/O) is conceivable.

The clearance of a task **e.clear** in the generated code is a call of the **free** function of C parameterized with the arguments of the translated task **e'**:

```

1 | free(e'.args)

```

3.1.3 Example code

The running example is chosen such as to be easy to understand in exchange for a realistic scenario. In this program for a range of numbers from 0 up to some threshold the cardinality of the set of factors is calculated in parallel:

```

1 | #constant threshold = 40;
2 | exported int32 main(int32 argc, string[] argv) {
3 |   // every task calculates the factor count for one number
4 |   Task<int32*>[threshold] tasks;
5 |   for (int8 i = 0; i < threshold; ++i) {
6 |     tasks[i] = |calcFactors(i + 2)|;
7 |   } for
8 |   // ...
9 |   return 0;
10 | } main (function)

```

The generation to C99 code yields the following intermediary helper code¹⁴:

```

1 | // generic declarations module
2 | exported struct Task {
3 |   void* args;
4 |   (void*)=>(void*) fun;
5 | };
6 | // user-defined module
7 | struct Args_a0a0b0b { // note the arbitrary suffix

```

¹³ Whereas in C for every struct type **T** a typedef has to be defined in order to reference this type directly with **T** instead of **struct T** in mbeddr this definition is done implicitly.

¹⁴ Mbeddr specific details have been reduced in order to enhance the legibility of the code

```

8 | int8 i;
9 | };
10 | void* parFun_a0a0b0b(void* voidArgs) {
11 |     int32* result = malloc(sizeof(int32));
12 |     Args_a0a0b0b* args = ((Args_a0a0b0b*) voidArgs);
13 |     *result = calcFactors((args)->i + 2);
14 |     return result;
15 | } parFun_a0a0b0b (function)
16 | inline Task taskInit_a0a0b0b(int8 i) {
17 |     Args_a0a0b0b* args_a0a0b0b = malloc(sizeof(Args_a0a0b0b));
18 |     args_a0a0b0b->i = i;
19 |     return (Task){ args_a0a0b0b , :parFun_a0a0b0b };
20 | } taskInit_a0a0b0b (function)

```

The generated struct contains exactly one element for the referenced variable in the task expression. A new reference to this element replaces the corresponding reference in the expression embraced by the task when it is copied into the parallel function. The initialization function allocates memory on the heap and uses it to save the value of the variable. The content of the main function simply becomes:

```

1 | Task[threshold] tasks;
2 | for (int8 i = 0; i < threshold; ++i) {
3 |     tasks[i] = taskInit_a0a0b0b(i);
4 | } for

```

TODO: Figure out argument deletion and write about it here

3.2 Futures

Whenever a task **t** is run, as will be shown, a *future* is generated. Futures in ParallelMbeddr are based on Halstead's definition of a future[11]. A future is a handle to a running task that can be used to retrieve the result of this task from within some other task **u**. As soon as this happens the formerly in parallel running task **u** joins **t** which means that it waits for **t** to finish execution in order to get its result value. The asynchronous execution is, thus, synchronized.

3.2.1 Design

The syntax **e** of expressions in mbeddr is extended by¹⁵:

e ::= ... | **e.run** | **e.result** | **e.join**

As with tasks the type of a future parameterized by its return type:

t ::= ... | *Future*<**t**>

e.run denotes the launch of task **e** whereas **e.result** joins a future **e** and returns its result. The last expression **e.join** can be used to join tasks that return nothing. These properties are reflected in the typing rules:

$$\begin{array}{ccc}
 \text{Future} \frac{e \vdash \text{Task}\langle t \rangle}{e.\text{run} \vdash \text{Future}\langle t \rangle} & \text{FutureResult} \frac{e \vdash \text{Task}\langle t^* \rangle}{e.\text{result} \vdash t^*} & \text{FutureJoin} \frac{e \vdash \text{Task}\langle \text{void} \rangle}{e.\text{join} \vdash \text{void}}
 \end{array}$$

As will be shown in the next section a **result** returns a pointer to a heap-managed value. Hence the programmer has to take of freeing the value eventually.

3.2.2 Translation

A future type **Future**<**t**> is translated to a generic **struct** that contains a handle to the thread, a storage for the result value—which is dropped for futures of type **Future**<**void**>—and a flag that indicates whether the thread is already finished:

¹⁵ If the expression **e** has a pointer type the dots (.) are replaced by arrows (->).

```

1 | exported struct Future {
2 |     pthread_t pth;
3 |     boolean finished;
4 |     void* result;
5 | };

```

For every task and future expression shown above a generic function reflects the semantics in the translation. The **run** of a task involves taking a task, creating a pthread with the task's function pointer and arguments and generating a future with the initialized thread handle¹⁶:

```

1 | exported Future runTaskAndGetFuture(Task task) {
2 |     pthread_t pth;
3 |     if ( task.argsSize == 0 ) {
4 |         pthread_create(&pth,0,task.fun,0);
5 |     } else {
6 |         void* args = malloc(task.argsSize);
7 |         memcpy(args,task.args,task.argsSize);
8 |         pthread_create(&pth,0,task.fun,args);
9 |     }
10 |     return ( Future ){ .pth = pth };
11 | } runTaskAndGetFuture (function)

```

The code shows that the arguments to be provided to the thread are copied onto a new location on the heap although they already reside on the heap as was shown in the previous section (TODO: backref). It is necessary to do so in order to avoid a dangling pointer. These could arise when a task is cleared before running out of scope so that the arguments get deleted while the running task instance, the declared thread is not finished, yet. Furthermore generally every thread needs its own copy of the data in case it modifies it. A corresponding function called **runTaskAndGetVoidFuture** is generated for futures that return nothing. The signature of **pthread_create** indicates how the result of a threaded function can be received. It expects a function pointer of type **void* -> void*** which is the reason why the function generated for a task is equally typed. The result is, thus, a generic **void** pointer. This implies that the threaded function could generally return the address of a stack-managed value, i.e. a local variable. Since the existence of the value after thread termination could not be guaranteed a dangling pointer[23] could emerge. The only safe alternative that fits the task-future structure well is to allocate memory on the heap and return the address of this memory (TODO: back-ref to parFun). The translation of the result retrieval is:

```

1 | exported void* getFutureResult(Future* future) {
2 |     if (!future->finished) {
3 |         pthread_join (future->pth, &(future->result));
4 |         future->finished = true;
5 |     } if
6 |     return future->result;
7 | } getFutureResult (function)

```

The **else** block reflects the usual future semantic. First the future is used to join the thread which blocks the execution until the thread is finished. Additionally the result is copied into the designated slot of the future. The result is at last returned. In POSIX a thread can only be joined once; every subsequent call causes a runtime error. In order to allow the user to request the result multiple times nevertheless the **finished** flag is used to decide whether a join should happen. The same basic structure can be found in the translation of the **join** function for a future of type **Future<void>**. The main difference is the missing result-related code:

```

1 | exported void joinVoidFuture(VoidFuture* future) {
2 |     if (!future->finished) {
3 |         pthread_join (future->pth, null);
4 |         future->finished = true;
5 |     } if
6 | } joinVoidFuture (function)

```

¹⁶ Obviously the thread handle is copied into the **Future**. This is safe as can be seen when looking at the POSIX function **pthread_t pthread_self(void)** which also returns a copy of a thread handle. This useful property is worth mentioning since it does not hold for all POSIX related data structures as will become clear in the synchronization section (TODO: ref).

Both aforementioned generated functions take their future parameters by address. This is necessary to make the setting of the future data work. Otherwise only copies of the provided future arguments would be filled with data which would clearly not be intended by the programmer. This necessity in turn does not assort well with chained future expressions like:

```
1 || Task<int32*> task = |(int32)23|;
2 || int32* result23 = task.run.result;
```

In this sample code the result of the future is requested before without being stored and accessed via address. Hence the code contradicts the previously given definition of the translation of **result**. A first caveat would be to change the line to:

```
1 || int32* result23 = (&(task.run)).result;
```

This on the other hand is not allowed because **task.run** is no lvalue[21, pp. 147-148] which disallows the utilization of the address operator. In order to allow for such chainings the unmodified code two wrapper functions, one for each **join** and **result**, are provided. These functions each take a future by argument, thus binding it to an adressable location, and call above corresponding functions in turn:

```
1 || exported void* saveFutureAndGetResult(Future future) {
2 ||     return getFutureResult(&future);
3 || } saveFutureAndGetResult (function)
4 ||
5 || exported void saveAndJoinVoidFuture(VoidFuture future) {
6 ||     joinVoidFuture(&future);
7 || } saveAndJoinVoidFuture (function)
```

By making use of the presented functions the reductions of **e.run**, **e.join** and **e.result** (with: **e'** is the reduced value of **e**) straightforwardly become function calls thereof:

1 runTaskAndGetFuture(e')	1 runTaskAndGetVoidFuture(e')
1 getFutureResult(&e')	1 joinFuture(&e')

3.2.3 Example code

The running factors example can now be extended with future-related expressions:

```
1 || // futures is an array of futures that on
2 || // each return a pointer to a heap-managed value of type int32
3 || Future<int32*>[threshold] futures;
4 || for (int8 i = 0; i < threshold; ++i) {
5 ||     futures[i] = tasks[i].run;
6 || } for
7 ||
8 || int32*[threshold] results;
9 || for (int8 i = 0; i < threshold; ++i) {
10 ||     results[i] = futures[i].result;
11 ||     printf ("fibonacci[%d] = %d\n", i, *(results[i]));
12 || } for
```

The sample translation contains the aforementioned generic definitions for future handling. The expressions become simple function calls:

```
1 || Future[threshold] futures;
2 || for (int8 i = 0; i < threshold; ++i) {
3 ||     futures[i] = runTaskAndGetFuture(tasks[i]);
4 || } for
5 ||
6 || int32*[threshold] results;
7 || for (int8 i = 0; i < threshold; ++i) {
8 ||     results[i] = ((int32*) getFutureResult(&futures[i]));
9 ||     printf ("fibonacci[%d] = %d\n", i, *(results[i]));
10 || } for
```

3.3 Shared memory

The previous chapters introduced the means to enable parallel execution of code in terms of tasks and futures. Still missing is the communication between tasks. The communication model of choice for ParallelMbeddr is shared memory. The reason for this choice follows from the objectives of the model: it should offer a reasonable performance, considering that it is supposed to be used in embedded systems; it should be safe by design in order to avoid the trip hazards that are involved with low-level synchronization approaches like mutexes. Transactional memory seems to be not ready for the embedded domain for performance reasons. By following argumentation message passing does not offer profound advantages in comparison to shared memory if the access to the shared memory is controlled in a sane way. Usually message passing forbids shared memory between two parallel XX of execution. Communication is then realized via sent messages. Strict separation of memory does not fit the usual C workflow concerning pointer arithmetic. Therefore some form of memory sharing would have to be introduced into a message passing model in order to reduce performance loss. As this would lead to the same problems that the general shared memory model already suffers the opposite way is chosen: Instead of introducing shared memory in a message passing model a shared memory model is designed on top of which message passing can ever be attached in order to simplify the communication between tasks.

Memory that is to be shared between two tasks must be explicitly declared by an according type. A variable of this type denotes a *shared ressource*. Thus, a shared ressource can be regarded as a wrapper of data that is to be shared. In order to make use of a shared ressource it has to be synchronized first. Specific language elements are used to access and change the value of a shared ressource.

3.3.1 Design

The ressources to be shared are typed with the shared ressource type:

$t ::= \dots | \text{shared}\langle u \rangle | \text{shared}\langle \text{shared}\langle u \rangle * \rangle$
 $u ::= t \quad u! = t*$

The type parameterization denotes the base type of a shared type, i.e. the type of the data that is wrapped by a shared ressource. Due to reasons that will be explained in the SAFETY CHAPTER a shared ressource may have an arbitrary base type that does not denote a pointer to a value that is not shared¹⁷. Further restrictions apply to shared types which are also investigated in the aforementioned section. The same applies to the **.set** expression by which the value of a shared ressource can be modified; the value can be retrieved via **.get**:

$e ::= e.\text{get} | e.\text{set}(e)$

$$\text{SharedGet} \frac{e \vdash \text{shared}\langle t \rangle}{e.\text{get} \vdash t} \quad \text{SharedSet} \frac{e \vdash \text{shared}\langle t \rangle \quad e' \vdash t' \quad t' <: t}{e.\text{set}(e') \vdash \text{void}}$$

The syntax stmts of statements in mbeddr is extended by the synchronization statement:

$\text{stmt} ::= \dots | \text{sync}(\text{res}, \dots, \text{res}) \{ \text{stmt} \dots \text{stmt} \}$

where **res** denotes the syntax of possible synchronization references. Each synchronization reference **res** wraps a reference to a shared ressource. It can either be of type **shared<t>** or of type **shared<t>***. A shared ressource can be synchronized as is or be named¹⁸:

$\text{res} ::= e | e \text{ as } [\text{resName}]$

The latter allows the programmer to refer to the result of an arbitrary complex expression which evaluates to a shared ressource inside the **sync** statement. Hence, a named ressource can be seen as syntactic sugar for a local variable declaration of a specific type. The scope of a named ressource is restricted to the synchronization statement; it can be referenced from anywhere inside the abstract syntax tree (AST) of the synchronization statement.

The type of such a reference is given by the corresponding named synchronization reference under the condition that **[resName]** is a descendant of the statement list in the abstract syntax tree (AST) of the code. Thus, the scope of a named synchronization ressource is restricted to the synchronization statement list.

In contrast to Java's synchronization blocks (TODO: google reference) the synchronization of tasks is not computation oriented but data oriented. The crucial difference is that a synchronized block **A** in Java is only protected against simultaneous executions by multiple threads. Thus, it is valid to access the data that is involved in **A** by some other computation whose protecting block (if any) is completely unrelated to **A**. Since low-level data races

¹⁷ Differently said: A pointer wrapped in a shared ressource must point to a shared ressource itself.

¹⁸ text

can obviously not be safely excluded with this scheme ParallelMbeddr ties the protection to the data that shall be shared. Every shared resource is therefore protected separately but application-wide. Concluding, consider two synchronization blocks which are about to be executed in parallel. If they contain synchronization references which overlap in terms of their referenced shared resources their executions will be serialized:

Kommentar von Bastian

Maybe make diagram

```
1 | shared<int32> value;
2 | shared<int32>* valuePointer = &value;
3 | shared<double> other;
4 |
5 | // simultaneous executions
6 | sync(value) { value.set(0) } sync(other, value) { value.set(0) }
```

==>

```
1 | // serialized executions, not necessarily in this order
2 | sync(value) { value.set(0) }
3 | sync(other, value) { value.set(0) }
```

The possibility to refer to multiple shared resources in the synchronization list of a synchronization statement is not mere syntactic sugar for nested synchronization statements. Instead the semantics of a synchronization list is that all referenced shared resources are synchronized over at once, but with a possible time delay. Hence, deadlocks by competing synchronization statements are avoided.

As a result of the fact that generally access to shared resources is resource-centric, a value—wrapped in a shared resource—which contains nested shared resources is independently protected from the latter. Therefore a shared resource of a struct with a shared member **b** is independently synchronized from **b**:

Kommentar von Bastian

Maybe make diagram

```
1 | struct A {
2 |     int32 a;
3 |     shared<int32> b;
4 | }
5 | shared<A> sharedA;
6 | shared<int32>* b;
7 | sync(sharedA) { b = &(sharedA.get.b); }
8 | // simultaneous executions which will not affect one another
9 | sync(sharedA) { sharedA.get.a = 0; } sync(b) { b->set(1); }
```

3.3.2 Implementation

In order to fully understand the translation of synchronization statements the translation of shared types is given first. For the implementation of shared types in C two main solutions are conceivable which differ in the coupling that they exhibit between the data that is to be shared and the additional data required for access restriction, i.e. synchronization. Nevertheless any solution must make use of additional data that can be used to synchronize two threads which try to read or write the shared data. To this end the most basic synchronization primitive, the mutex was chosen: each protected data item is assigned exactly one.

In the first solution the data to be shared is stored as if no protection scheme existed, at all. Additionally all mutexes that are created by the application are stored in one global map which indexes each mutex by the memory address of its corresponding shared datum. This approach offers the advantage that access to the data itself is not influenced by the mutex protection: Every reference to the value of a shared resource **e.get** can directly be translated into a reference to the wrapped value. Additionally, since the mutexes are globally managed all data that is returned by a library can be made (pseudo-) synchronization safe: E.g. if a pointer to an arbitrary memory location *loc* is returned the pointed-to address can be used to create a new mutex and add a mapping to the global mutex map. However, this on-the-fly protection of memory locations can incur synchronization leaks: The compiler cannot guarantee that addresses returning functions with unknown implementation will not leak

their return values to some other computation which accesses the according memory unsynchronized. This implies that such protection would only be safe if any reference to `loc` was wrapped in some shared resource which in this scenario is not feasible. Hence, the design was chosen to not allow for such protection and consequently a global map would not be beneficial in this regard. A map solution would entail a space-time tradeoff. For illustrative purposes consider Google's C++ `dense_hash_map`¹⁹ provides comparatively fast access to its members but imposes additional memory requirements to slower hashmap implementations²⁰.

The second solution for the implementation of shared types keeps each shareable datum and its mutex together: An instance of a struct with member fields for both components is used in place of the bare datum to be shared. In contrast to the aforementioned solution a reference to the value `e.get` needs one level of indirection via the struct instance. On the contrary the access of a mutex is simplified. As with the value it can be retrieved by a member access to the corresponding struct field whereas the map solution requires a map lookup to get the mutex (plus additional delay to make any access to the map thread-safe). The computational overhead imposed by a member lookup is deemed negligible in the overall application performance. The space required for the struct equals that of the individual fields plus additional padding[17, pp. 303 ff.]. The latter depends on the size of the data to be stored. In order to keep the padding small smart member ordering should be applied.

For this work the struct solution was chosen in order to keep the computational complexity of mutex lookups small (and deterministic -> TODO: ref) while not imposing too much space overhead and datum lookup overhead. For each kind of shared type `shared<t>` with the translated basetype `t'` a separate struct is generated:

```
1 struct SharedOf_t {
2     pthread_mutex_t mutex;
3     t' value;
4 }
```

Any nested shared types are, hence, translated first. For implementation reasons nested `typedefs` and constants used in array types are also resolved in this process²¹. If the base type of the shared type is a generic C type the struct declaration is safed in a generic module. Otherwise it is stored in a module that is specifically created for the module that declares the base type in order to reduce the legibitly mitigations of the generated modules. In order to be visible in the generated module the base type declaration is lifted into this module. Should the separation of modules prove useless it could be easily removed in the future. A local variable declaration `shared<t> v;` is then reduced to:

```
1 SharedOf_t v;
```

Prior to any usage of a mutex it must be initialized first. This is done implicitly in order to free the programmer from this task. **TODO: Code aendern: deletion reparieren**

TODO: Code aendern: pro Typ eine Init-Funktion, nicht wie bisher pro Variable.
Letzteres zusaetzlich fÃ¼r Arrays von SharedTypes

TODO: beschreiben...

TODO: deletion aehnlich

TODO: PrÃ¼fen, ob mutex-init-Reihenfolge richtig ist

`ParallelMbeddr` does not prevent the programmer from structuring the synchronization statements in such a way that a task will synchronize a shared variable multiple times (*recursive synchronization*). The following code depicts such behavior:

```
1 shared<int32> sharedValue;
2 sync(sharedValue) {
3     sync(sharedValue) {
4         sharedValue.set(42);
5     }
6 }
```

Since each synchronization statement locks the mutexes of the referred shared resources (see below for details) a recursive synchronization results in a *recursive lock* of the corresponding mutex. Mutexes as defined by the POSIX

¹⁹ http://goog-sparsehash.sourceforge.net/doc/dense_hash_map.html

²⁰ <http://incise.org/hash-table-benchmarks.html>

²¹ Although the resolution of `typedefs` and constants impede corresponding changes made by the programmer in the translated C code this is not deemed an issue since generally changes should always be made from within `mbeddr`, i.e. on the original code.

standard must be specifically initialized in order to allow for this behavior²²: A mutex attribute that specifies the recursiveness must be defined and initialized first. It can then be used by arbitrarily many mutexes. For this purpose an application-wide attribute is defined in a generic module that is imported by all user-defined modules. It is initialized at the beginning of the main function:

```
1 // inside the generic module:
2 extern pthread_mutexattr_t mutexAttribute
3 // at the beginning of main:
4 pthread_mutexattr_settype(&mutexAttribute, PTHREAD_MUTEX_RECURSIVE);
5 pthread_mutexattr_init(&mutexAttribute_0);
```

Every synchronization statement is reduced to its statement list—as a block—surrounded with calls to functions that control the synchronization of the mutexes. The reduction becomes:

1 sync(e) stmt_list	==>	<pre>1 startSyncFor1Mutex(&e.mutex); 2 stmt_list' 3 stopSyncFor1Mutex(&e.mutex);</pre>
1 sync(e_1, ..., e_n) stmt_list	==>	<pre>1 startSyncForNMutexes(&e_1.mutex, ..., &e_n.mutex); 2 stmt_list' 3 stopSyncForNMutexes(&e_1.mutex, ..., &e_n.mutex);</pre>

The statements are kept inside their statement list block in order to keep the scope of local variables inside synchronization statements. The block is reduced to another block where control flow breaking statements may be preceded by a similar call of the **stopSyncForNMutexes()** function as was shown above. Let *s* be a synchronization statement and *c* be a control flow breaking statement which is nested on some level in the AST of *s*' statement list. Then *c* is preceded with a call to **stopSyncForNMutexes()** if one of the following cases hold:

- *c* is a *return* statement and refers to a function or a closure whose AST contains *s*;
- *c* is a *break* statement and refers to a loop or a *switch* statement case whose AST contains *s*;
- *c* is a *continue* statement and refers to a loop whose AST contains *s*.

For each arity of synchronization resources separate versions of the **start-** and **stopSyncForNMutexes** functions are declared inside a generic C module. The latter kinds straightforwardly redirect their mutex parameters to calls of the **pthread_mutex_unlock** function:

```
1 // the corresponding function for exactly one mutex is skipped, here
2 void stopSyncForNMutexes(pthread_mutex_t* mutex_1, ..., pthread_mutex_t* mutex_n) {
3     pthread_mutex_unlock (mutex_1);
4     ...
5     pthread_mutex_unlock (mutex_n);
6 }
```

TODO: erkläre livelock, wait-lock(!)obstruction free und busy-wait protocol in basics

Abstracted over the details of the actual implementation, synchronization statements synchronize their resources atomically as was mentioned in the preceding design section. Since one or more mutexes can be tentatively locked by multiple threads simultaneously specific contention management has to be taken care of. The illusion of atomic synchronization is realized by an implementation of the obstruction-free busy-wait protocol *Polite*. In order to resolve conflicts *Polite* uses exponential backoff. The according backoff function is explained further down. The synchronization function tries to lock every mutex as given by its arguments. On failure it releases every mutex that was locked so far, uses the backoff function to delay its execution for a randomized amount of time and repeats afterwards. This scheme enables competing threads to proceed.

²² By default a recursive lock results in undefined behaviour because a default mutex does not have a lock count which is required to make recursive locks work: http://linux.die.net/man/3/pthread_mutex_trylock

```

1 exported void startSyncForNMTuxes(pthread_mutex_t* mutex_0, ..., pthread_mutex_t* mutex_n) {
2     uint8 waitingCounter = 4;
3     uint16 mask = 0;
4     uint32 seed = (uint32)(uintptr_t) &waitingCounter;
5     while (true) {
6         if ([| pthread_mutex_trylock (mutex_0) |] != 0) {
7             backoffExponentially(&waitingCounter, &mask, &seed);
8         } else if ([| pthread_mutex_trylock (mutex_1) |] != 0) {
9             [| pthread_mutex_unlock (mutex_0) |];
10            backoffExponentially(&waitingCounter, &mask, &seed);
11        } ...
12    } else if ([| pthread_mutex_trylock (mutex_n) |] != 0) {
13        [| pthread_mutex_unlock (mutex_n-1) |];
14        ...
15        [| pthread_mutex_unlock (mutex_0) |];
16        backoffExponentially(&waitingCounter, &mask, &seed);
17    } else {
18        break;
19    }
20 }
21 }

```

The backoff realized by Polite randomized delays the execution by less than $limit = 2^{n+k}$ ns[24]. n denotes the retry counter and k denotes some constant offset which can be machine-tuned. When n reaches a specific threshold m it is reset to 0. The randomized wait time of the exponential backoff is used to avoid livelocks which could happen if two threads would repeatedly compete for the same resources and delay their execution for equal amounts of time. In the current implementation **backoffExponentially()** the offset k is set to 4 and the threshold m is set to 17. Thus, maximum delays of about 100 ms (specifically 131 ms) are allowed²³. Note that **backoffExponentially()** keeps its main state inside the **startSyncForNMTuxes()** function which will therefore be re-initialized before the execution of every synchronization block:

```

1 inline void backoffExponentially(uint8* waitingCounter, uint16* mask, uint32* seed) {
2     *mask |= 1 << *waitingCounter;
3     randomWithXorShift(seed);
4     struct timespec sleepingTime = (struct timespec){ .tv_nsec = *seed & *mask };
5     nanosleep(&sleepingTime, null);
6     *waitingCounter = (*waitingCounter + 1) % 17 || 4;
7 }

```

The generation of the pseudo-randomized delay is realized via utilization of the Marsaglia's Xorshift random number generator[18]:

```

1 void randomWithXorShift(uint32* seed) {
2     *seed ^= *seed << 13;
3     *seed ^= *seed >> 17;
4     *seed ^= *seed << 5;
5 }

```

The generator was chosen for its high performance, low memory consumption and thread safety due to the utilization of the stack-managed seed parameter as opposed to the global state usage of the standard C random generator **rand()**.

TODO: sync => start/stop Mutex (start zu Beginn, stop am Ende und evtl. vor Kontrollfluss brechenden statements)

²³ The search for machine- or application-specific optimal offsets and thresholds is a task for future enhancements of ParallelMbeddr.
